Correlation between the Superconducting Transition Temperature
and Anisotropic Quasiparticle Scattering in Tl$_2$Ba$_2$CuO$_{6+\delta}$

(Received 31 January 2007; published 7 September 2007)

Angle-dependent magnetoresistance measurements are used to determine the isotropic and anisotropic components of the transport scattering rate in overdoped Tl$_2$Ba$_2$CuO$_{6+\delta}$ for a range of $T_c$ values between 15 and 35 K. The size of the anisotropic scattering term is found to scale linearly with $T_c$, establishing a link between the superconducting and normal state physics. A comparison with results from angle resolved photoemission spectroscopy indicates that the transport and quasiparticle lifetimes are distinct.

Understanding the normal state is regarded as a key step in resolving the problem of high temperature superconductivity (HTSC), yet establishing any clear correlation between the two has proved difficult. Most empirical correlations to date, such as the Uemura plot [1] and the linear scaling of the magnetic resonance mode energy with $T_c$ [2], are associated with the superconductivity. Homes’ law, linking $T_c$ with the product of the superfluid density and the dc conductivity (at $T_c$) [3], is a rare example of a correlation linking the two states, though this also could be viewed as a consequence of superconducting (SC) gap formation rather than a normal state property [4]. Transport properties, particularly for current in-plane, appear very much tied to the $T_c$ parabola (for a review see [4]) but any direct correlation between transport and superconductivity has not yet been found. Finally, the precise doping dependence of the pseudogap and its relation to $T_c$ remains a controversy [5].

Here we identify a new correlation between the normal and superconducting states using a bulk transport probe, namely, interlayer angle-dependent magnetoresistance (ADMR) [6]. ADMR has provided detailed Fermi surface (FS) information for a variety of one- and two-dimensional (2D) metals [7–9]. Recently the technique was extended to incorporate basal-plane anisotropy and to reveal the temperature $T$ and momentum ($k$) dependence of the scattering rate $\Gamma(T, k)$ in heavily overdoped (OD) Tl$_2$Ba$_2$CuO$_{6+\delta}$ (Tl2201) [10]. There $\Gamma(T, k)$ was found to consist of two components, one isotropic and quadratic in $T$, the other anisotropic, maximal near the saddle points at $(\pi, 0)$ and proportional to $T$.

In this Letter, ADMR measurements at $T = 40$ K and magnetic field $\mu_0H = 45$ T are compared for a number of OD Tl2201 crystals with $T_c$ values between 15 and 35 K. The strength of the anisotropic scattering extracted from the analysis is found to scale linearly with $T_c$, appearing to extrapolate to zero at the doping level where superconductivity vanishes. This finding implies that the anisotropic scattering mechanism is intimately related to the mechanism of HTSC. In marked contrast to recent results from angle resolved photoemission spectroscopy (ARPES) [11,12], no sign reversal of the anisotropy in the quasiparticle lifetime is inferred. Finally, our results shed new light on the doping evolution of both the in-plane resistivity $\rho_{11}(T)$ and the Hall coefficient $R_H(T)$ in OD cuprates.

For this study a total of six self-flux grown crystals (typical dimensions $0.3 \times 0.3 \times 0.03$ mm$^3$) were annealed at temperatures $300^\circ$C $\leq T \leq 600^\circ$C in flowing O$_2$ and mounted in a $c$-axis quasi-Montgomery configuration. The ADMR were measured on a two-axis rotator in the 45 T hybrid magnet at the National High Magnetic Field Laboratory in Florida using a conventional four-probe ac lock-in technique. The orientation of the crystal faces was indexed for a number of crystals using a single crystal x-ray diffractometer.

The first and third panels of Fig. 1 show polar ADMR data $\Delta \rho_{11}/\rho_{11}(0)$ (normalized to their zero-field value) at different azimuthal angles $\phi$ (relative to the Cu-O-Cu bond direction) for two crystals Tl15Kb and Tl32K (the numbers relate to their $T_c$ values). Though the two sets of data look similar, there are some key differences [13]. First $\Delta \rho_{11}/\rho_{11}(0)$ is significantly larger for the lower $T_c$ crystal. Second, for polar angles $|\theta| \sim \pi/2$, Tl32K shows much less $\phi$-dependence and finally, near H $|| c$ ($\theta = 0$), the Tl15Kb curves are more rounded. As shown below, these features are caused by the higher $T_c$, less overdoped sample(s) possessing a significantly larger basal-plane anisotropy in $\omega_c \tau$ (the product of the cyclotron frequency and the transport lifetime).

In order to extract information on the FS and $\omega_c \tau$, we carried out a least-square fitting of the data using the Shockley-Chambers tube integral form of the Boltzmann transport equation modified for a quasi-2D metal with a fourfold anisotropic scattering rate $1/\tau(\phi) = (1 + \alpha \cos^4 \phi)/\tau^0$ and anisotropic in-plane velocity $v_{11}(\phi)$, incorporated via $1/\omega_c(\phi) = (1 + \beta \cos^4 \phi)/\omega_c^0$ [10,14]. The sign of $\alpha$ defines the location of maximal scattering. The FS wave vector $k_F(\theta, \phi)$ was parameterized by the

lowest-order harmonic components satisfying the body-centered-tetragonal symmetry of Tl2201 [8],

\[
k_F(\theta, \varphi) = k_{00} - k_{40} \cos 4 \varphi - k_{21} \cos (k_c \varphi) \sin 2 \varphi \\
- k_{61} \cos (k_c \varphi) \sin 6 \varphi - k_{101} \cos (k_c \varphi) \\
\times \sin 10 \varphi,
\]

where \(k_c\) is the \(c\)-axis wave vector and \(c\) the interlayer spacing. An eightfold term \(k_{60} \cos (8 \varphi)\) had a negligible effect on the parameterization and was therefore not included in the fitting procedure. Note that the \(c\)-axis warping parameters \(k_{21}, k_{61},\) and \(k_{101}\) are small compared to \(k_{00},\) the radius of the cylindrical FS (about the zone corners), and \(k_{40}\), its in-plane squareness, and only ratios (e.g., \(k_{61}/k_{21}\)) can be determined to good accuracy. To minimize the number of free parameters, we fix \(k_{101}/k_{21} = k_{61}/k_{21} - 1\) such that \(t_1(\varphi)\) vanishes at \(\varphi = 0^\circ\) and \(45^\circ\) [9,15] and fix \(k_{00}\) using the empirical relation \(T_c/T_{c}^{\text{max}} = 1 - 82.6(p - 0.16)^2\) with \(T_{c}^{\text{max}} = 92\) K and \((\pi k_{00}^2)/(2\pi /a)^2 = (1 + p)/2\) [16]. \(\beta\) depends largely on our choice of \(k_{61}/k_{21}\) with the best least-square values giving \(\beta = 0 \pm 0.1\) for \(0.6 \leq k_{61}/k_{21} \leq 0.8\) for all samples [17]. The sum \(\alpha + \beta\) was much less sensitive to variations in \(k_{61}/k_{21}\) and for simplicity, we assume hereafter \(\omega_c(\varphi) = \omega_c^0\). For completeness however, in Table I we list the values for \(\alpha + \beta\).

The best fits, shown in the panels to the right of each data set, are all excellent and the four remaining fitting parameters displayed in Table I appear well constrained due to the wide range of polar and azimuthal angles studied [18]. Within our experimental resolution, the FS parameters appear to have negligible doping dependence. Moreover, the projected in-plane FS is found to be in good agreement with a recent ARPES study on the same compound [12]. The anisotropy parameter \(\alpha\) increases with rising \(T_c\), while \(\omega_c^0\) shows the opposite trend (reflecting the overall reduction in the ADMR in Fig. 1).

Our previous analysis of Tl15Ka implied the existence of both isotropic and anisotropic components in the scattering rate in OD Tl2201 [10]. Accordingly we split \(1/\omega_c^0 \tau(\varphi)\) into two components \(\gamma_{iso}^0 = (1 - \alpha)/\omega_c^0 \tau^0\) and \(\gamma_{aniso}^0 = 2\alpha/\omega_c^0 \tau^0 \cos^2 2 \varphi\). In Tl15Ka, \(\gamma_{iso}^0 \sim A + BT^2\), due to a combination of impurity and electron-electron scattering, while \(\gamma_{aniso}^0 \sim CT\) (setting \(\beta = 0\)) [10], the microscopic origin of which has yet to be identified. The doping \((T_c)\) dependence of \(\gamma_{iso}^0\) and \(\gamma_{aniso}^0\) (at \(T = 40\) K) are shown in the top and bottom panels of Fig. 2, respectively. Although we cannot say anything about the \(T\) dependence of the two components, it is clear that while \(\gamma_{iso}^0\) is essentially doping independent, \(\gamma_{aniso}^0\) shows a clear linear scaling with \(T_c\), extrapolating to zero at the onset of superconductivity (on the OD side). Within a standard rigid band model, one would expect anisotropy in \(\nu_F(\varphi)\) and hence in \(\omega_c(\varphi)\) to increase with doping as the FS at the Brillouin zone boundary approaches the saddle points. The fact that the data show the opposite trend is therefore significant and justifies our key assumption that the basal-plane anisotropy in Tl2201 is dominated by anisotropy in \(1/\tau(\varphi)\) [10,17], which, surprisingly for such highly OD samples, remains significant (the absolute anisotropy \(\geq 2\) for Tl35K at \(T = 40\) K).

This empirical correlation between \(\gamma_{aniso}\) and \(T_c\) has several implications for the normal state of OD cuprates. First, given that the carrier concentration is varying only weakly (as \(1 + p\)) in this doping range, it is apparent that

![Fig. 1](color online). Angle-dependent magnetoresistance sweeps for two overdoped Tl2201 single crystals with \(T_c\) of 15 K (Tl15Kb—left side) and 32 K (Tl32K—right side) measured at 40 K and 45 T. The least-square fits to the data are displayed on the right of each plot. The labels refer to the azimuthal angle of the magnetic field with respect to the Cu-O-Cu bond direction.

the marked change in the absolute value of resistivity with doping [19] is due primarily to a decrease in anisotropic scattering. Second, the observation of cyclotron motion over the full FS volume implies that there are no pseudogapped regions of FS in OD Ti2201 for \( x \approx 0.24 \) [5]. Whilst one might argue that such a large applied field could suppress any pseudogapping in our crystals [20], our conclusion is consistent with the observation of metallic \( \rho_{11}(T) \) in zero field [9,21]. The c-axis pseudogap, inferred from interlayer tunneling [20] and scanning tunneling microscopy [22] on \( \text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta} \), is therefore a nonuniversal feature of OD cuprates.

Last, and most important, the suppression of superconductivity on the OD side looks to coincide with the disappearance of \( \gamma_{\text{aniso}} \). This conclusion is consistent with the observation in nonsuperconducting \( \text{La}_{1.7}\text{Sr}_{0.3}\text{CuO}_4 \) of a strictly \( T^2 \) resistivity [23] (provided \( \gamma_{\text{aniso}} \) remains \( T \)-linear) and a vanishing of \( T \) dependence of the resistive anisotropy \( \rho_{\perp}/\rho_{ab}(T) \) [24,25] and indicates an intimate relation between the anisotropic scattering and HTSC. Our findings contrast markedly with the doping evolution of the imaginary part of the quasiparticle self-energy \( \text{Im}\Sigma \) inferred from ARPES. Here the nodal/antinodal quasiparticle anisotropy is seen to vanish [26] or even reverse its sign [11,12] before superconductivity is suppressed on the OD side. ARPES-specific issues such as resolution, background subtraction and matrix-element effects are not believed to be important here [27]. One thus needs to ask the question whether the two probes are in fact measuring the same quantity. Direct comparison of the scattering rates deduced from ADMR (this study and Ref. [21]) and ARPES [12] in Ti2201 (\( T_c \approx 30 \) K) shows that the former is more than 1 order of magnitude smaller. Since ARPES measures the quasiparticle lifetime, small-angle scattering must contribute significantly to \( \text{Im}\Sigma \). Interlayer transport in cuprates, however, is also believed to be determined by a product of single-particle spectral functions on adjacent planes [28] and may thus be similarly susceptible to small-angle scattering. Given that ADMR is a bulk probe, we conjecture that the anomalously large linewidths seen in ARPES most probably arise from additional scattering at the (cleaved) surface.

As stated above, \( \gamma_{\text{aniso}}(T) \) could account for both \( R_H(T) \) and \( \rho_{ab}(T) \) in Ti115Ka at low \( T \) [10]. To simulate the doping evolution of \( \rho_{ab}(T, p) \) and \( R_H(T, p) \) in Ti2201, we adopt a simple one-parameter-scaling model and calculate \( \rho_{ab}, R_H \) (and the in-plane magnetoresistance \( \Delta\rho_{ab}/\rho_{ab} \)) using the Jones-Zener form of the Boltzmann equation for a quasi-2D FS [29]. First, \( k_0 \) and \( k_{ab} \) are fixed using the values for Ti115Ka listed in Table I and the scaling relation [16] described earlier. Second, we assume that \( 1/\omega_c\tau(T, \varphi) \) has the same form as Ti115Ka for all crystals, i.e., \( 1/\omega_c\tau(T, \varphi) = \gamma_{\text{iso}}(T, \varphi) + \gamma_{\text{aniso}}(T, \varphi) = A + BT^2 + C(p)\cos^22\varphi \), where \( C(p) = C(\text{Ti115Ka})T_c(p)/15 \) [10]. Finally, the anticipated return to isotropic scattering at high \( T \) is simulated by inclusion (in parallel) of a maximum scattering rate \( \Gamma_{\text{max}} = \langle v_F(\varphi)/a \rangle \) (where \( a \) is the in-plane lattice spacing) in accord with the Ioffe-Regel limit [29]. In this way, \( \gamma(T, \varphi) \) saturates at different points on the FS at different \( T \). Such anisotropy in the onset of saturation (of \( \text{Im}\Sigma(\omega) \)) has been seen in optimally doped \( \text{La}_{2-x}\text{Sr}_x\text{CuO}_4 \) [30].

The resultant simulations for \( R_H(T, p) \) and \( \rho_{ab}(T, p) \) are presented in Fig. 3 for \( T_c = 10, 25, 50, \) and 80 K. Despite there being no free parameters (\( C(p) \) is fixed by \( T_c \)), the \( R_H(T) \) plots show qualitative agreement with the published data (solid symbols, [19,21,31]). The \( p \) dependence of \( \rho_{ab}(T) \) is also consistent with experiment, where the exponent \( n \) of \( \rho_{ab} (= \rho_0 + vT^n) \) is found to evolve smoothly from 1 to 2 between optimal doping and the SC/non-SC boundary [19]. Finally, \( \Delta\rho_{ab}/\rho_{ab} \) (top left panel for \( T_c = 25 \) K) displays the correct magnitude and \( T \)-dependence [21]. This correspondence, plus the fact that our simulations capture the marked increase in the magnitude of \( R_H \) for what are relatively small changes in carrier concentration, suggests that anisotropic scattering is a dominant contributor to the \( T \) and \( p \) dependence of \( R_H \) across the OD regime, while the monotonic variation of \( R_H(T, p) \) is incompatible with a sign reversal of the scattering rate anisotropy near \( p = 0.2 \) inferred from ARPES [11,12].
as for possible origins of the observed anisotropy, real-space (correlated) electronic inhomogeneity [32] is one possible candidate though as yet, no measurements have been performed on heavily OD non-SC cuprates to establish any possible link between inhomogeneity and superconductivity. Interactions with a bosonic mode are another possibility, though given the strong angle and doping dependence, presumably not phonons. More likely candidates include spin, charge (stripe), or d-wave pairing fluctuations which all disappear with superconductivity [25,33,34]. The preservation of the crystalline c axis with respect to the rotational platform. The inclusion of a coordinate axis rotated around the platform axis can account for such a distortion and has been added to our fitting routine though has a negligible effect on the parameters obtained.

Note for Ti15Ka, top line in Table I, data have been obtained for only one azimuthal angle [10].

The asymmetry around $\theta = 0$ arises from slight misalignment of the crystalline c axis with respect to the rotational platform. The inclusion of a coordinate axis rotated around the platform axis can account for such a distortion and has been added to our fitting routine though has a negligible effect on the parameters obtained.

Note for Ti15Ka, top line in Table I, data have been obtained for only one azimuthal angle [10].
